activity in vitro and is able to increase carotenoid production in recombinant yeast and a breeding pedigree. The resulting amino acid exchange in a highly conserved region of PSY provides increased catalytic storage roots. A single nucleotide polymorphism present only in yellow-rooted cultivars cosegregates with colored roots in the flux of carbon through carotenogenesis, thus leading to the accumulation of colored provitamin A carotenoids in PSY modification are being applied to increase their production and accumulation to fight vitamin A deficiency disorders. We cassava cultivars contain a limited amount of provitamin A carotenoids, both conventional breeding and genetic modification are being applied to increase their production and accumulation to fight vitamin A deficiency disorders. We show here that an allelic polymorphism in one of the two expressed phytoene synthase (PSY) genes is capable of enhancing the flux of carbon through carotenogenesis, thus leading to the accumulation of colored provitamin A carotenoids in storage roots. A single nucleotide polymorphism present only in yellow-rooted cultivars cosegregates with colored roots in a breeding pedigree. The resulting amino acid exchange in a highly conserved region of PSY provides increased catalytic activity in vitro and is able to increase carotenoid production in recombinant yeast and Escherichia coli cells. Consequently, cassava plants overexpressing a PSY transgene produce yellow-fleshed, high-carotenoid roots. This newly characterized PSY allele provides means to improve cassava provitamin A content in cassava roots through both breeding and genetic modification.

INTRODUCTION

In plants, carotenoids perform essential physiological functions in photosynthesis and as precursors of regulatory molecules, such as abscisic acid (Schwartz et al., 1997) and strigolactones (Bouwmeester et al., 2007; Gomez-Roldan et al., 2008; Umehara et al., 2008). Their formation is initiated by reactions catalyzed by carotenoid cleavage dioxygenases (CCDs; for review, see Bouvier et al., 2005; Moise et al., 2005; Auldridge et al., 2006). In animals, including humans, provitamin A carotenoids containing at least one unsubstituted β-ionone ring serve as precursors of retinoids, synthesized through cleavage at the central C15-C15′ double bond, which is catalyzed by the β-carotene cleavage monooxygenase 1 (reviewed in Moise et al., 2005).

Because of the widespread prevalence of vitamin A deficiency diseases in the tropics (WHO, 2009), efforts are underway to increase the provitamin A content of edible plant tissues, an approach commonly referred to as biofortification (for review, see Mayer et al., 2008). This can be achieved through breeding, if sufficient genetic variability for the trait is present, but requires genetic modification in its absence. Golden Rice, for example, was the logical consequence of the absence of carotenoid production in the endosperm of the rice (Oryza sativa) grain (Ye et al., 2000; Paine et al., 2005). A further barrier to breeding is sterility, such as in commercial banana (Musa spp) cultivars, or where breeding is complicated, as for some vegetatively propagated crops, such as potato (Solanum tuberosum). Cultivated potato suffers from serious inbreeding depression upon self-pollination and represents a highly heterozygous tetraploid. Consequently, genetic transformation was employed to increase provitamin A content in potato tubers (Diretto et al., 2007). Provitamin A carotenoids in cassava (Manihot esculenta) have been increased threefold through conventional breeding; however, the heterozygous nature of the crop renders varietal recovery difficult, and long breeding cycles slow down the progress of this endeavor (Rojas et al., 2009).

Cassava is quoted as the fifth most important staple crop worldwide but ranks first in many arid regions, such as in sub-Saharan Africa. Like with other staples, the cassava storage root is rich in starch but poor in protein and micronutrients like iron, zinc, and provitamin A. Yellow-rooted cultivars producing provitamin A carotenoids are rare, although some yellow landraces have been identified in Amazonia (Ferreira et al., 2008; Nassar et al., 2009); most breeding populations are white rooted. Because of the difficult and unwieldy breeding of cassava, genetic modification is being considered as a viable option but was hindered in the past by less-well-developed basic knowledge of the crop compared with other staples, such as maize (Zea mays), wheat (Triticum aestivum), and rice. It is only during recent years that research has been done to identify storage root-specific promoters (Zhang et al., 2003; Arango et al., 2010a; Beltrán et al., 2010) and that genomic sequence information has become available (http://www.phytozone.net/cassava).
It is desirable to gain insight into the carotenoid biosynthetic pathway of a given plant tissue to be able to design cDNA constructs capable of overcoming rate limitations of the biosynthetic pathway. This has become possible thanks to the almost complete molecular elucidation of the pathway (for review, see DellaPenna and Pogson, 2006).

In plant tissues exhibiting low-level carotenoid production, the limiting factor is commonly the expression level of phytoene synthase (PSY), which catalyzes the first carotenoid-specific reaction of prenyl lipid metabolism in the plastid (Figure 1). This has been shown to be the case in canola (Brassica napus; Shewmaker et al., 1999) and Arabidopsis thaliana seeds (Lindgren et al., 2003). PSY expression can be driven to levels at which b-carotene crystals are formed, as in Arabidopsis cells and in carrot (Daucus carota) roots (Maass et al., 2009). However, there are cases where additional transgenes are needed to raise carotenoid production levels, such as in Golden Rice, in which the carotene desaturase CrtI had to be introduced along with PSY (Burkhardt et al., 1997; Ye et al., 2000; Schaub et al., 2005) or potato, in which a mini pathway of three carotenoid genes was necessary to achieve high levels of production (Diretto et al., 2007). As shown in Figure 2, the pronounced differences in carotenoid content in the roots of these cultivars (see Supplemental Table 1 online) were not reflected in the expression levels of these genes. Consequently, the rate limitation in W and C must stem from differential expression of pathway genes not considered in the analysis or be based on entirely different principles.

**RESULTS**

**No Correlation between Root Color and Expression of Major Carotenoid Biosynthesis Genes**

To determine the rate-limiting step in the carotenoid biosynthetic pathway in storage roots, the expression levels of major carotenoid biosynthesis genes was determined for cultivars differing in carotenoid content. The cultivars analyzed were CM 3306-4 with low, CM 2772-3 with intermediate, and MBRA 253 with high root carotenoid content (from here on referred to as white [W], cream [C], and yellow [Y], respectively). The real-time RT-PCR study included the two expressed cassava PSY genes (Arango et al., 2010b), phytoene desaturase (PDS), z-carotene desaturase (ZDS), lycopene b- and e-cyclase (LCY-b and LCY-e), and b-carotene hydroxylase (b-HYD). CCD1 was included as a representative of an unspecific carotenoid degrading enzyme. As shown in Figure 2, the pronounced differences in carotenoid content in the roots of these cultivars (see Supplemental Table 1 online) were not reflected in the expression levels of these genes. Consequently, the rate limitation in W and C must stem from differential expression of pathway genes not considered in the analysis or be based on entirely different principles.

---

**Figure 1.** The Carotenoid Biosynthetic Pathway in Plants.

Note that PSY is central, catalyzing the first committed biosynthetic step in carotenogenesis. IPP, isopentenyl-diphosphate; DMAPP, dimethylallyl-diphosphate; GGPP, geranylgeranyl-diphosphate; GPP, geranyl-diphosphate synthase; PDS, phytoene desaturase; ZISO, z-carotene isomerase; ZDS, z-carotene desaturase; CRTISO, carotene isomerase; LCY, lycopene b- and e-cyclase. The dashed arrow represents multiple enzymatic steps.

**Figure 2.** Carotenoid Content of Three Different Cassava Landraces and Expression Levels of Carotenoid Biosynthetic Genes.

(A) Carotenoid content in 9-month-old field-grown roots of W (cv CM 3306-4), C (cv CM 2772-3), and Y (cv MBRA 253). White, xanthophylls; black, b-carotene; gray, phytoene.

(B) RNA expression levels of carotenoid biosynthetic genes in the roots analyzed in (A). Transcript levels were determined by real-time RT-PCR, normalized to 18S rRNA levels, and are expressed relative to the expression level of one sample from W.

Error bars in (A) and (B) represent the SE of three biological replicates.
An Allelic Variant of One Cassava PSY Gene Defines Cassava Root Color

Sequencing of the two cassava full-length PSY cDNAs (PSY1 and PSY2) revealed the occurrence of single nucleotide polymorphisms (SNPs) in PSY2 (see Supplemental Figure 1 online). Two of these, SNP1 and SNP2, were present in the Y cultivar, defining the alleles PSY2-Y-1 and PSY2-Y-2 (Figure 3), while the C cultivar contained only SNP2. SNP3 was restricted to W and was homonymous and therefore not considered further. By contrast, PSY2-Y-1 carried a G521C nucleotide substitution equivalent to an R174T amino acid exchange, and PSY2-Y-2 carried a C572A nucleotide substitution leading to an A191D amino acid exchange. The authenticity of these sequence differences was verified by RT-PCR amplification and sequencing of the individual cDNA variants. Because of the positive color/SNP correlation, we hypothesized that the SNPs discovered were crucial for root color formation.

To investigate further, we took advantage of a breeding population selected for their wide variation in provitamin A root phenotypes (Figure 4). The population was based on an initial cross between cultivars other than those mentioned above, namely, the white-rooted cultivar MMAL 66 and the yellow-rooted MBRA 1A. SNP1 was not detected in either parent. The R174T exchange was therefore ruled out as a cause for the color phenotype. By contrast, SNP2 (resulting in A191D) was present in the yellow-rooted parent and absent from the white. Self-pollination of white F1 (GM 708-20) and yellow F1 (GM 708-63) genotypes resulted in contrasting S1 families. A total of 37 S1 individuals made up family AM 697 (from the W genotype GM 708-63) genotypes resulted in contrasting S1 families. A total of 37 S1 individuals made up family AM 697 (from the W genotype GM 708-63) and the yellow-colored cassava landrace (Me2-Y-1 and Me2-Y-2). The relevant allelic variants present in the yellow-colored cassava landrace (Me2-Y-1 and Me2-Y-2). The relevant

The A191D Exchange in PSY Results in Increased Enzymatic Activity

The open reading frames (ORFs) coding for PSY_A191 or PSY_D191 were independently coexpressed in yeast cells supplemented with geranylgeranyl-diphosphate synthase (GGPS) from white mustard (Sinapis alba) to produce the PSY substrate geranylgeranyl-diphosphate (GGPP). HPLC quantification revealed that PSY_D191 (present in yellow-rooted cassava) produced approximately twice as much phytoene as the PSY_A191 version of white-rooted cultivars, indicating increased enzymatic activity (Figure 5A). To provide further evidence, an Escherichia coli–based system expressing GGPS and the bacterial carotene desaturase CrtI was used, and the conversion of phytoene into red-colored lycopene was measured photometrically. These experiments were complemented by coexpressing the PSY genes from daffodil (Narcissus pseudonarcissus; Np-PSY), Arabidopsis thaliana; Zm. Zea mays. Identical amino acids are shown with a gray background.
amino acid exchange by an approximate doubling of lycopene production at comparable protein levels, similar to the equivalent cassava PSY versions tested in yeast. The coexpression of the mutagenized Zm-PSY1 resulted in a 20% higher lycopene production.

To confirm that increased enzymatic PSY activity is the underlying cause of the yellow phenotype, we used the wild type and the A-to-D mutagenized At-PSY in vitro (Figure 3C). The system consisted of purified N-His6-GGPS (Kloer et al., 2006) delivering the PSY substrate GGPP and the N-His6-fused PSY versions in a 2:1 GGPS/PSY molar ratio in a biphasic (liposome-containing) assay (Figure 6). The reaction was started with [1-14C]isopentenyl-diphosphate (IPP) and dimethylallyl-diphosphate. Phytoene was quantified by liquid scintillation counting. Corroborating the previous results, the mutagenized PSY version led to approximately threefold higher specific activities.

PSY Is Rate Limiting in the Carotenoid Biosynthetic Pathway of Cassava Roots

Given that improved enzymatic activity of PSY can increase the flux through the carotenoid pathway in cassava roots, we hypothesized that the root-specific overexpression of any PSY should result in the formation of colored carotenoids by increasing phytoene synthesizing capacity. To test our hypothesis, we constructed the binary vector pCAS-Phyt harboring an RbcS transit peptide-bacterial PSY gene (TP-CrtB) under the control of the cassava CP1 promoter (Beltrán et al., 2010). Agrobacterium tumefaciens–mediated transformation was used with the white-rooted cassava cultivar TMS 60444. Transgenics were confirmed by DNA gel blot analysis (see Supplemental Figure 2 online). After 6 months of growth, carotenoid analysis was performed on roots using quantitative HPLC (Table 1). This showed that all transgenic events had a higher carotenoid content over the wild-type control. Among these, event 12 roots had the deepest orange color (Figure 7). However, the carotenoid pattern showed accumulation of a substantial fraction of the noncolored carotene intermediates phytoene and phytofluene (see Discussion). Thus, in cassava roots, PSY activity, replaceable by increased PSY expression levels, represents an important control point in the biosynthesis of downstream carotenoids.

Figure 4. SNP2 (D191) Cosegregates with Colored Roots in a Cassava Pedigree.

Cultivars MBRA1A (yellow-rooted) and MMAL66 (white-rooted) were crossed using MMAL66 as the male parent. Siblings of this cross were self-pollinated, and the resulting offspring grown in the field. Randomly selected white and colored roots were harvested after 9 months of growth and analyzed for carotenoid content and composition. Leaf DNA was used for SNP2 identification through sequencing of the respective PCR-amplified PSY region. The presence of Asp at position 191, replacing the conserved Ala, was decisive for carotenoid accumulation (see Supplemental Table 2 online).

Figure 5. Production of Phytoene by PSY Variants in Yeast and E. coli Cells.

(A) Cassava PSY2D191 from the Y cultivar and PSY2A191 from the W cultivar were individually expressed in yeast cells coexpressing the GGPS cDNA from S. alba. The phytoene formed was quantified by HPLC. Cell lysate (30 μg protein) was used to estimate PSY levels using an anti-At-PSY antibody. The levels of HA-tagged GGPS were determined using anti-HA antibodies (loading control).

(B) Production of lycopene in recombinant E. coli cells. Site-directed mutagenesis was performed to exchange the wild type A for D (as given in Figure 3C) with cDNAs from N. pseudonarcissus (Np-PSY), Arabidopsis (At-PSY), and Z. mays (Zm-PSY1). Wild-type and mutated PSY versions were expressed separately in an E. coli strain expressing GGPS and the bacterial phytoene desaturase (CrtI), thus capable of producing lycopene.

Error bars in (A) and (B) represent the SE of three biological replicates. Immunoblots were conducted using anti-6*His-Tag antibodies and cell lysate corresponding to 1.5 μg protein per lane.
DISCUSSION

The enzyme PSY has been shown to be rate determining in carotenogenesis for a number of different plant tissues. Paine et al. (2005) also showed that the source of the PSY transgene was critical for the increased carotenoid production in Golden Rice 2. Whereas the PSY paralogs from daffodil, tomato (Solanum lycopersicum), and pepper (Capsicum annuum), known to enable high carotenoid overproduction in chromoplasts, were fairly ineffective, those from rice (not developing chromoplasts) and maize were in this case the best to bolster carotenoid production in the grain endosperm. Because of the high similarity between plant PSYs, sequence variations affecting the catalytic efficiency of the enzyme can be as subtle as one single amino acid difference, as we are able to show here.

In the past, association mapping and linkage analysis have pointed to alleles favoring a desired carotenoid composition. In different maize genotypes, polymorphisms capable of increasing the proportion of provitamin A carotenoids have been identified in the genes for lycopene ε-cyclase (Harjes et al., 2008) and β-carotene hydroxylase 1 (Yan et al., 2010). A single SNP leading to an amino acid replacement in a conserved position of LCY-b, and probably leading to impaired catalytic function, was found to define red- and yellow-fleshed watermelon (Citrullis vulgaris) due to the accumulation of lycopene and cyclic carotenoids, respectively (Bang et al., 2007). A single amino acid substitution in the enzyme LCY-e is responsible for the introduction of one or two ionone rings (Cunningham and Gantt, 2001).

The SNP in PSY2 is associated with root color due to increased PSY catalytic activity, as we showed using yeast and E. coli as heterologous expression systems as well as through in vitro enzymology with the purified enzymes. All of the PSYs from different organisms we tested in vitro did not accept GGPP as substrate, but required its de novo synthesis and delivery through GGPS. Therefore, it is not possible to determine the $K_m$ for PSYs. Moreover, all PSY-GGPS combinations we used so far showed a variable degree of leakiness (i.e., the release of GGPP as a side-product). However, there is no available evidence for the free in vivo diffusion of the extremely amphipathic intermediate GGPP, which is thought to be channeled into the different prenyl lipid biosynthetic routes (Figure 1). Evidence has been presented in the older literature for the existence of a PSY complex comprising at least GGPS and PSY (reviewed in Cunningham and Gantt, 1998). The observation that the increment of increased activity upon mutagenesis depends on the basal activity of the respective wild-type PSY (Figure 5B) together with the fact that increased pathway flux was also observed in cassava (where PSY interacts with a cassava GGPS; thus, a different GGPS than the one from $S. alba$ that we used in vitro), and the in vitro data obtained are altogether in support of increased intrinsic PSY activity as the underlying cause for provitamin A accumulation.

Finally, a metabolite channel may exist between PSY and PDS. Although the presence of protein-free liposomes (as used here) are sufficient for effective phytoene production in vitro, the product pattern in the transgenic cassava events generated suggests that protein–protein interaction may occur between PSY and PDS. Large amounts of phytoene accumulated upon the expression of the bacterial PSY (CrtB, Table 1), which shares only 40% similarity with cassava PSYs. This low level of similarity might result in an impaired interaction between the two proteins,
thus producing membrane-bound phytoene that is less accessible to PDS. Alternatively, PDS may simply represent the subsequent rate-limiting step in the pathway of the cultivar used, which is revealed upon relieving the first.

A threefold increase in the in vitro conversion rate contrasts with an up to 20-fold increase in the carotenoid content of roots carrying the PSYD191 allele. The other in vivo systems used, yeast and E. coli, showed a clear increase in lycopene and β-carotene production, although more in tune with PSY activity. The reason for the discrepancy between our in vitro and in vivo observations most probably lies in the long incubation time (i.e., the potential of the carotenoid biosynthesis pathway to be active over several months of secondary root development). In the presence of a comparatively lower β-carotene turnover, accumulation can take place at high levels. Kinetic considerations, such as substrate concentrations substantially below the $K_m$ as generally present in cells, and other unknown factors determining the biochemical environment of amyloplasts, however, render any quantitative comparisons between the in vitro and the in vivo situations difficult.

The A191D amino acid exchange is in a highly conserved sequence region of PSY (Figure 3). The sequence diversity of PSY1 in grasses has been assessed (Fu et al., 2010), revealing a hot spot of nonsynonymous substitutions residing in a region located ~115 amino acids closer to the N terminus than the exchange reported here. In addition, allelic PSY1 variants of durum wheat were found to be associated with high endosperm carotenoid contents (Zhang and Dubcovsky, 2008; Singh et al., 2009), but none of these mutations were in a position equivalent to the one reported here. Whereas A191D appears to be a rare variant, its activity-increasing effect was similar in all the mutagenized PSY homologs investigated. Therefore, we conclude that the mutation has generally applicable structural and functional implications. Crystallization of PSY is currently underway to elucidate the catalytic mechanisms involved.

The PSY mutation described here provides a previously unknown means for the improvement of cassava provitamin A content. A transgenic approach employing root-specific promoters and targeting relevant cassava varieties can take advantage of this PSY variant. Alternatively, the finding presented here can provide breeders with the necessary tools to increase the levels of provitamin A carotenoids of cassava roots using marker-assisted selection.

### METHODS

#### Cassava Plant Materials and Genetic Transformation

Cassava (Manihot esculenta) plants were grown in the field at the International Center for Tropical Agriculture (CIAT). Earlier studies identified Table 1. Carotenoid Profile Determined by HPLC from Roots of 6-Month-Old Field-Grown Transgenic Plants Expressing the Bacterial PSY CrtB (CP1:TP-CrtB)

Figure 7. Overexpression of PSY Is Sufficient to Enable the Accumulation of Colored Carotenoids in Cassava Roots.

Yellow roots represent transformation event no. 12, and white roots represent the wild-type control. A photograph of representative peeled roots is shown in the top panel; transverse roots sections are shown below.
that a hybrid family from the cross of two landraces (MMAL 66 × MBRA1A) segregated widely for carotenoid contents. Two contrasting individuals with high and low carotenoid content were selected from this full sib family (GM 708-20 and GM 708-63) and self-pollinated to produce S1 families AM 697 (from GM 708-20) and AM 702 (from GM708-63). In addition, four landraces were analyzed: CM 3306-4 and MPER 183 with low, CM 2772-3 with an intermediate, and MBRA 253 with a high root carotenoid content.

Cassava was transformed as described elsewhere (Beltrán et al., 2010) using embryogenic callus of the genotypetype TMS 60444 (coded as Nga 11 in the germplasm collection at CIAT).

DNA Gel Blot Analysis

Cassava genomic DNA was isolated according to Sambrook and Russell (2001). Fifteen micrograms of genomic DNA were digested with HindIII and fractionated electrophoretically through a 0.8% (w/v) agarose gel before capillary transfer and immobilization on nylon membrane (Hybond N*; GE Healthcare). A PCR fragment containing 470 bp of the CttBnos terminator region (see Supplemental Table 3 online for primer information) was amplified from the vector pCAS-Phyt and DIG-dUTP labeled using a PCR DIG probe synthesis kit (Roche Diagnostics) according to the manufacturer’s instructions. Hybridization was performed according to standard procedures.

cDNA Cloning, Vector Construction, and Expression Analysis

cDNA sequences from cassava PSY1, PSY2, and PSY3 (Arango et al., 2010b), PDS, ZDS, LCY-b, LCY-a, b-HYD, and CCD1 were amplified by RT-PCR using cultivar CM 3306-4 (for primers and accession numbers, see Supplemental Table 3 online). The use of primer pair SNP-sen and SNP-asen allowed amplifying PSY1 and PSY2 fragments encompassing SNP1 and SNP2; primer SNP-seq was used for sequencing.

For construction of the binary vector pCas-Phyt, the TP-CttB gene (Diretto et al., 2007) encoding the PSY from Pantoea ananatis fused with the pea (Pisum sativum) RbcS transit peptide (TP; Misawa et al., 1993) was isolated from pTrio1, a pBluescript KS derivative, using SacI and Ncol. The fragment thus obtained was ligated into the accordingly digested pCas-Cttl, a pBluescript derivative harboring a TP-Cttl expression cassette driven by the cassava Cttl promoter (Beltrán et al., 2010), to yield pCas-Cttl. The plasmid pCas-Cttl was digested with Clal, blunt-ended with T4-DNA polymerase, and treated with Xbal to isolate CPT-TP-Cttl. The fragment thus obtained was then ligated into Pmiil/ Xbal-digested pCAMBIA1303.2 (Canberra) to yield pCas-Phyt.

Transcript levels were determined by real-time RT-PCR using 6FAM-labeled TaqMan probes for detection of PSY, PDS, ZDS, LCY-b, and LCY-a; those of b-HYD and CCD1 were determined by SYBR green (for primers and probes, see Supplemental Table 3 online). The 18S rRNA levels were quantified with the eukaryotic 18S rRNA endogenous control kit (Applied Biosystems) and used for normalization. The relative quantity of the transcripts was calculated using the comparative threshold cycle method (Livak, 1997). Data were normalized first to the 18S rRNA level of the corresponding sample and then calculated relative to one sample from the white-rooted cassava cultivar.

Carotenoid Analysis

Carotenoids were extracted from 500 mg of lyophilized ground roots and analyzed by HPLC (Welsh et al., 2008). Phytoene from yeast cells was extracted accordingly, but 100 µL of β-carotene (Sigma-Aldrich; 60 µg mL⁻¹ in acetone) were added as an internal standard. Extracts were saponified prior to HPLC analysis. Photometric quantification of cyclic carotenoids was done using ε452nm = 134,500 liters mol⁻¹ cm⁻¹. Escherichia coli cell pellets were extracted twice with chloroform/methanol (2:1, v/v). Lycopene concentration was determined photometrically in petroleum benzene using ε452nm = 185,230 liters mol⁻¹ cm⁻¹.

Heterologous Expression of PSY Variants in Yeast and E. coli Cells

For the investigation of cassava PSY2 versions in vivo, the split-ubiquitin system was used according to Obrdlik et al. (2004), including vector and yeast strains described herein. The ORF of Sinapis alba GGPS, with its putative transit peptide truncated as indicated by Welsch et al. (2000), was cloned in vivo in the vector pNHgate using the yeast strain THY.APS. The resulting vector pNubGGPsdTP encoded GGPS as a translational fusion with an N-terminal HA tag. The ORFs of PSY2 allelic versions, with their putative transit peptides truncated (Arango et al., 2010b), were cloned (primers MePSY2B1 and MePSY2B2) in the vector pMexYGgate using the yeast strain THY.AP4. Cells carrying pNubGGPsdTP were mated with each of the THY.AP4, each transformed with either of the PSY2 variants. Diploid cells were grown and subcultured in synthetic complete medium containing adenine and histidine. The phytoene formed was quantified by HPLC.

For the coexpression of GGPS with PSYs of different origins and Cttl from P. ananatis in E. coli strain BL21-CodonPlus-RIL, the DUET vector set (Novagene-Mercer) was used. pET-GGPS contained the S. alba GGPS ORF, with its putative transit peptide truncated. It was obtained by subcloning a BarnHI/SalI fragment from pGGPS (Welsch et al., 2000) into the accordingly digested vector pETDuet-1. For pCDF-Cttl, the Cttl ORF was amplified from pBaa2 (Ye et al., 2000) with the primers CttlEcoc and CttlHind, the PCR fragment digested with EcoRI and HindIII and subcloned into the accordingly digested vector pCDFDuet-1. pRSF-GGPS contained the ORF of PSY versions, with their putative transit peptide removed. Vectors coding for the A/D amino acid exchange equivalent to cassava PSY2 were generated by overlapping extension PCR using the corresponding pRSF vectors with wild-type sequences as templates. Primers are given in Supplemental Table 3 online; positions of the first amino acid and of the A/D exchange are as follows: At-PSY, Arabidopsis thaliana, start, #58, A187D; Np-PSY, Narcissus pseudonarcissus, start, #65, A184D; Zm-PSY1, Zea mays, start, #52, A174D.

Overnight grown cultures from E. coli cells transformed with pET-GGPS, pCDF-Cttl, and one PSY version in pRSF were subcultured in 50 mL of fresh medium and grown to OD600nm = 0.5 at 37°C. Expression was induced with 0.5 mM isopropyl-b-D-thiogalactopyranoside, and cultures were incubated at 28°C. Two, three, and four hours after induction, the OD600nm was recorded; 45 mL of culture spun down and used for lycopene extraction as described above. The mean value from these measurements was recorded.

Immunoblot Analysis, Protein Purification, and Enzymatic Assays

E. coli or yeast cells in PBS were disrupted with a French press. After centrifugation (3100g), the protein concentration was determined in the supernatant. Proteins (30 µg yeast lysate; 1.5 µg E. coli lysate) were separated by SDS-PAGE and blotted onto polyvinylidenefluoride membranes. Immunodetection of PSY2 in yeast protein was performed with anti-At-PSY antibodies (Maass et al., 2009). GGPS in yeast was detected using an anti-HA-tag antibody (Cell Signaling Technology). His6-GGPS and His6-PSY2 were detected with an anti-6xHis-Tag antibody (Sigma-Aldrich).

GGPS from S. alba was purified as published (Kloor et al., 2006). The Arabidopsis PSY ORF with its transit peptide sequence removed at position #58 was subcloned into pCOLDI (Takara-Clontech) to yield an N-terminal His6 fusion as described (Maass et al., 2009). From this plasmid, a second vector coding for an Asp instead of Ala at position #187 was generated by overlapping extension PCR (for primers, see Supplemental Table 3 online). Cell pellets from 1 liter of induced culture were resuspended in 20 mL lysis buffer (50 mM phosphate buffer, pH 7.6, 1 mM MgCl2, and 1 mM TCEP (Tris [2-carboxyethyl]phosphine
hydrochloride) and kept for 30 min on ice after adding 10 units of benzonase and lysozyme (Sigma-Aldrich). After sonication and centrifugation (16,000g, 40 min), the resulting pellet was washed twice with water, once with 1% (v/v) Triton X-100, and once with 2 M urea. Inclusion bodies obtained were solubilized in 10 mL of 6 M GuHCl containing 1 mM TCEP and treated with 10,000 g centrifugation (10,000 g, 20 min), 2 mL of Co2+ Fractogel (Merck) was added. The resin was washed with 50 mM Tris-HCl, pH 7.6, 300 mM NaCl, 1 mM TCEP, 1 mM MgCl2, and 0.035% (w/v) LDAO and then dialyzed against 500 mL of dialysis buffer (50 mM Tris-HCl, pH 7.6, 600 mM NaCl, 1 mM TCEP, 1 mM MgCl2, and 0.035% (w/v) LDAO) for 3 h.

Fifteen micrograms of recombinant purified His6-At-PSY and 22 µg of purified His6-GGPS were incubated in 4.5-mL reaction buffer (100 mM Tris-HCl, pH 7.6, 2 mM MnCl2, 1 mM TCEP, 0.08% (v/v) Tween 80, 10 mM decylamine gation (16,000 g) and kept for 30 min on ice after adding 10 units of benzonase and lysozyme (Sigma-Aldrich). After sonication and centrifugation (10,000 g, 20 min), 2 mL of Co2+ Fractogel (Merck) was added. The resin was washed with 50 mM Tris-HCl, pH 7.6, 300 mM NaCl, 1 mM TCEP, 1 mM MgCl2, and 150 mM NaCl. After centrifugation (10,000 g, 40 min), the resulting pellet was washed twice with 2 M urea. Inclusion bodies obtained were solubilized in 10 mL of 6 M GuHCl containing 1 mM TCEP, 1 mM MgCl2, and 0.035% (w/v) LDAO, and treated with 100 mM EDTA for 20 min. After centrifugation, the supernatant was dialyzed against 500 mL of dialysis buffer (50 mM Tris-HCl, pH 7.6, 600 mM NaCl, 1 mM TCEP, 1 mM MgCl2, and 0.035% (w/v) LDAO) for 3 h.

Accession Numbers
Sequence data from this article can be found in the Genbank/EMBL/DDBJ databases under the following accession numbers: At-PSY, P37271; Np-PSY, PS33797; Zm-PSY1, P49005; CrbB, M87280; Os-PSY1, NP_0010558647; Os-PSY2, ABA99494; Os-PSY3, ACI62767; Sl-PSY1, EF534740; Sl-PSY2, EF534738; and S. alba GGPS, X86795. Cassava sequences were submitted to GenBank and received the following accession numbers: PDS, GU120072; ZDS, GU120073; LCY-b, GU120074; LCY-e, GU120075; b-HYD, GU120076; CCD1, GU120077; CCD4, GU120078; PSY2-W-1, GU111720; PSY2-W-2, GU111721; PSY2-Y-1, GU111722; and PSY2-Y-2, GU111723.

Supplemental Data
The following materials are available in the online version of this article.

Supplemental Figure 1. Allelic Variants of Cassava PSY2.

Supplemental Figure 2. DNA Gel Blot Analysis of Transgenic Cassava Events Transformed with pCAS-Phyt.

Supplemental Table 1. Carotenoid Content and Pattern of the Three Investigated Cassava Cultivars Differing in the Carotenoid Levels of Their Storage Roots.

Supplemental Table 2. Carotenoid Levels and SNP2 Presence in a Cassava Breeding Population.

Supplemental Table 3. Primers and Probes.

ACKNOWLEDGMENTS
This research was supported by the HarvestPlus research consortium, which received a grant from the Bill & Melinda Gates Foundation. The valuable contribution by Yaneth Ladinob and Danilo López (CIAT) is gratefully acknowledged. We thank Petr Obrdlik for providing the vectors and yeast strains for the split-ubiquitin system. We thank Jorge Mayer for his critical reading of the manuscript.

Received June 21, 2010; revised August 17, 2010; accepted September 20, 2010; published October 1, 2010.
